Education and equal opportunities among Liberian children

Running Title: Equal opportunities in Liberia

José Cuesta\textsuperscript{a} and Ana Abras\textsuperscript{b} *

\textsuperscript{a} World Bank and Georgetown Public Policy Institute, Georgetown University; Washington DC; US; \textsuperscript{b} World Bank, Washington DC, US

\textbf{Abstract:} This paper expands the analysis of equal opportunities by connecting traditional benefit incidence analysis of public spending with the human opportunity index, a distribution sensitive measure of access to public services. It also develops ex ante micro simulations to determine the cost of equalizing educational opportunities. This technique is applied to Liberia, a country devastated by civil war with serious educational enrollment gaps and policies highly dependent on international aid. Results from simulated increases in teachers' salaries, elimination of fee and non-fee costs and targeted public educational spending on rural schools all point to very modest redistributive effects but distinctive patterns of winners and losers among Liberian children.

\textbf{Keywords:} Equality of opportunities; education, redistribution; simulations; Liberia

\textbf{JEL classification:} D63, I24.

1. **Introduction**

Political and economic thinking remains divided about the extent to which public policies should be used to redress inequality. An early review in Barr (1987) shows how libertarians, liberals, socialists, Marxists and other collectivist views differ on the role that the state should play in reducing social and economic inequalities. Most recently, John Roemer’s “Equality of Opportunities” consolidates the increasing discontent among egalitarian political philosophers on what they consider excessive attention given to the state’s role to the detriment of personal responsibilities and the focus on outcomes—monetary incomes, for the most part—in the understanding of inequality. Under this view, inequality of outcomes due to differential effort is ethically acceptable, while that caused by circumstances beyond the control of individuals or that society accepts that individuals should not be responsible for is ethically unacceptable (Roemer et al. 2003: 540). It is only for the latter inequity that the state has ethical grounds to intervene and for fiscal policies to redress the situation.

Early work on equality of opportunities (Roemer 1998, Betts and Roemer 2001, Page and Roemer 2001, Roemer et al. 2003) primarily focused on the fiscal side of public interventions. Those analyses invariably included a fiscal policy tool, be it educational financing (Betts and Roemer 2001), taxation and transfers (Roemer et al. 2003) or unemployment insurance (Roemer 1998), and they asked fundamentally fiscal questions. For example, in Betts and Roemer (2001), the authors examine the extent to which redirecting educational public spending would contribute to narrow educational access across races in the US. More recent work has shifted the attention to the measurement of unequal opportunities—either constructing stochastic dominance tests or new indexes, such as the Human Opportunity Index. In addition, empirical work has started to include less developed countries (in both Sub-Saharan Africa and Latin America). Analytical changes have included the expansion of circumstances from race and parental
education to additional variables to account for social background and household demographics and to include children rather than (male) adults.

The purpose of this paper is to bring back the policy angle to the measurement and analysis of equality of opportunities. In doing so, this paper conducts two separate exercises. First, it expands one of the most used distributive analyses of public policies, benefit incidence analysis (BIA), and relates it to the concept of equality of opportunities. Second, it carries out ex-ante micro-simulations of alternative public policies and estimates their impacts on the distribution of educational opportunities for children in Liberia. Liberia is a case worth exploring for multiple reasons: a protracted civil war between 1989 and 2004 that devastated the country and shattered vulnerable groups, including children; a delicate fiscal position dependent on the vagaries of international aid; and only a few distributive analyses despite the existence of socioeconomic and fiscal data.

The present work differs from previous literature on equality of opportunity in that it does not control for effort (more precisely, it does not consider effort as a residual of one or two selected circumstances), but rather focuses entirely on the role that multiple circumstances play in generating unequal access to education. Also, the analysis integrates public policies as a de facto circumstance, that is, a decision that individuals have nothing to do with and cannot be responsible for and which most observers would agree should not matter for the legal right of children to access schools.

Results show that circumstances play a dramatic role in educational disparities among Liberian children, especially parental education, but also gender, orphanhood, birth order, location and exposure to conflict. Public spending on education does not appear capable of redressing the constraints that those circumstances pose to educational access, even after large
redistributive transfers among vulnerable groups or after net increases in public education transfers. The exercise in this paper is not a behavioral simulation, however, but rather a model that sheds light on the relevance of several constraints acting against a leveled field of equal opportunities. Results strongly indicate that the average impact on opportunities from substantial relative changes in spending may be limited. This is primarily due to the meager public budget on education. At the same time, opportunity impacts are not equally distributed among types of children, implying different patterns of winners and losers caused by interventions aimed at improving equal opportunities among children.

2. The distributive analysis of policies within the equality of opportunity approach

2.1. The analysis of equality of opportunity

Although the empirical literature on equality of opportunities is relatively recent, it has already branched out in several directions (Table 1). Works are classified into one of two categories: (I) normative studies with a clear policy objective, using either parametric or non-parametric empirical analyses on the impact of circumstances on some specific wellbeing objective; and (ii) measuring the extent of equality of opportunities in a given country or region as part of a diagnostic approach. Also, studies differ in analyzing just one or two or multiple circumstances and opportunities.

Roemer (1998) is the seminal reference. His framework comprises five concepts (Roemer et al. 2003). Objective is the goal that equal opportunities are expected to achieve. Circumstances are the attributes of an individual’s environment (either social, genetic or biological) that affect the achievement of the objective but that are beyond the control of the individual and for which society does not regard him or her responsible. Effort refers to individual behaviors and decisions
that, together with circumstances, determine the level of objective accomplished. *Instrument* refers to the policy—typically the provision of resources—used to equalise opportunities. *Type* is a set of individuals who all have the same circumstances. Equality of opportunities prevails when an objective or opportunity is achieved with the same level of effort across different circumstances. Analytically, Roemer’s work seeks the value of the instrument that equalises the value of the objective across types at any given degree of effort (Roemer et al. 2003, 542). Empirical applications of this approach are found in Betts and Roemer (2001), Roemer et al. (2003), or Bourguignon, Ferreira and Menendez (2007).

A second empirical approach is developed in Van der Gaer (1993), Ooghe et al. (2007), Hild and Voorhoeve (2004) and Cugneau and Mesplé-Somps (2009). It considers that there is equality of opportunities when the distribution of expected earnings is independent of social origins. Conditional expectations of earnings (or consumption as in Cugneau and Mesplé-Somps, 2009) are obtained from the distribution of average income estimated across several categories. These categories are typically determined by parental education and/or parental occupation and, in some cases, geographical location. Some versions of this approach, as in Cugneau and Mesplé-Somps (2009) or Cugneau and Cigneux (2008), use ‘intermediary’ variables to analyse the link between social origin and income/consumption (such as social position and education). They conclude that a significant part of difference in inequality of opportunity for income/consumption can be attributed to differences in intergenerational mobility linking parental education and occupation with sons’ education and occupation.

A third analytical approach develops non-parametric statistical tests, in particular, stochastic dominance tests. Leblanc, Pistolesi and Trannoy (2008) define equality of opportunity as the situation where income distribution conditional on social origin cannot be ranked
according to stochastic dominance criteria, using non-parametric statistical tests developed by Davidson and Duclos (2000) to compare generalised Lorenz curves. Again, social origin is defined by parental education and/or occupation. Leblanc, Pistolesi and Trannoy (2008) distinguish a risk component and a return component inspired in the original Oaxaca-Blinder decomposition of wage gaps in endowment and return differentials: the former assumes that within-type inequality is fully erased; the latter assumes that between-type inequality is removed. In addition, the paper develops the Gini Opportunity index, which computes the weighted sum of all the differences among areas of opportunity sets and then divided that sum by the mean income of the entire population. That makes the index independent of the wealth of a society, a convenient feature for international country comparison.

A final approach estimates the Human Opportunity Index (HOI) developed by Barros et al. (2009) and Molinas et al. (2010). The HOI has the clear analytical objective of measuring how equitably a society progresses towards universal access of basic opportunities. The index synthesises in a single indicator how close a society is to universal coverage in a given opportunity (as with standard coverage measurements), along with how equitably coverage of that opportunity is distributed. Opportunities are goods and services that constitute investments in children, thus increasing their human capital, such as primary education and adequate housing infrastructure. An equitable policy ensures that a child’s chance of accessing these key goods and services is not correlated with circumstances that are beyond their control, such as gender, parental background or ethnicity. The HOI ‘penalises’ the extent to which different circumstance groups (types in Roemer’s terminology) have different coverage rates: the penalty is zero if coverage rates among multiple circumstance groups are equal and is positive and increasing as differences in coverage among circumstance groups increase. The HOI is equality-sensitive and
Pareto-consistent. When access to an opportunity increases equally for all circumstance groups, the index increases proportionally. Changes in the HOI over time can be decomposed into changes in the distribution of circumstances in the population (composition effect), changes in coverage rates for all groups (scale effect), and changes in the degree of inequality of opportunity (equalization effect).

2.2. The analytical limitations of equality of opportunities

There are a number of limitations associated with the analysis of equality of opportunities. Primarily, the conceptual distinction between circumstance and effort has not been operationalised in practice with similar clarity. Effort has either been assumed to be a residual of circumstance or has been surpassed by restricting the focus of analysis to individuals who cannot be accountable for effort differences, that is, children. A result of this is the uncomfortable solution of luck being considered part of effort, as explicitly admitted by Roemer et al. (2003). Interpretations are even more troublesome when, for example, sex or race become effort variables, as they are deemed residuals of socioeconomic background captured solely by parental education or occupation.

A second limitation is the arbitrary selection of some key concepts. The distinction between circumstance and opportunity is not always sharp. Family income is typically considered a circumstance, but it also constitutes an opportunity—inasmuch as it contributes to the access of basic services—for the success in life of a child. Disability is clearly considered as a circumstance for a child, but having an able, healthy status is considered to be an opportunity for future success (or current success in school). Being exposed to or the victim of insecurity may be considered equally as a circumstance (in the same way as urban or rural residence) but
also as a lack of opportunity for children (when considering the potential effects on the physical and emotional development of the child).

Furthermore, what is ethically acceptable or desirable are conveniently made dependent on any society’s judgment. Thus, if a society considers that females should not be educated equally as males, then sex will not be incorporated as a circumstance in the analysis. And different judgments may appear frequently across different contexts, be it for religious reasons or in contexts of conflict and historical grievances among groups. This, ultimately, creates a sort of “quicksand” baseline since few circumstances may be universally agreed upon. As a result, comparability across countries may be troublesome.

Other limitation refers to the empirical application of measurements. Equality of opportunities in a given context is sensitive to the selection of peoples and objectives, as with any other social indicator (say, access coverage). However, the HOI is also sensitive to the set of circumstances selected as well as the set of opportunities considered. Nonetheless, Narayan and Hoyos’s (2012) results for almost 20 Sub-Saharan African countries substantiate that results tend to be robust to changes in definitions. In a similar vein, quality issues are hardly included in the analysis, both because it is an open-ended conceptual issue (whether an opportunity is simply access to a service or, rather, access to a quality service) but also because datasets typically lack the information to systematically include quality considerations.

From a policy point of view, equality of opportunities does not address the causes or motivations behind the distributive features of a policy. Rather, analyses have so far concentrated on determining how the distribution of an opportunity or objective (say, income or education attainment) changes after a policy is introduced in a rather static partial equilibrium set-up. How a policy affects intergenerational mobility within society is hardly estimated, although links
between the two concepts have been explicitly pointed out (see Bourguignon, Ferreira and
Menendez 2007 and references there). In addition, the depiction of policymaking so far has been
very simplistic, assuming for instance that taxation is modified to simplify tax rules—that is, a
flat rate is imposed to every type—or a similar increase in education spending for all children
across groups. In other words, the notion of fiscally feasible—affordability—has dominated the
analysis of more realistic, complex and multidimensional policies. As for the HOI, no application
to policymaking has been attempted so far, with efforts mainly directed to estimating and
comparing a set of comparable objectives across countries. The rest of this paper remedies this
gap by developing a method that links HOI with public spending.

3. Fiscal issues and equality of opportunities: method

Methodologically, the paper carries out three separate exercises (Table 2). First, it estimates the
HOI for access to education in Liberia for children aged 6-15. HOI is estimated in the World
Bank “tradition” following the techniques described in Table 1 and recently applied to Latin
America by Molinas et al. (2010). The set of circumstances relevant for Liberia and the selected
opportunity are defined and justified in section 4, below.

Second, the paper expands the traditional benefit incidence analysis into an “Opportunity
Benefit Impact Analysis” (Opp-BIA), that is, an incidence analysis of public educational
spending along the distribution of opportunities, and compares it with the “traditional” BIA
based on income distribution. Table 2 describes the steps for the analysis, which basically
consists of conducting the traditional BIA analysis over a distribution of children (age 6-15)
educational opportunities, proxied by the expected probability of access to school conditioned on
their circumstances.
The Opp-BIA has two main advantages over the traditional BIA. First, it allows focusing on the allocation of public resources in education against a concept of vulnerability directly related to education. This is preferred to working around an indirect concept of per head household income or consumption as done by BIA. In other words, it allows a sharper picture of the distribution of resources and opportunities directly associated to such resources. Second, it provides insights on how multiple factors (all those considered relevant circumstances) affect the distribution of educational resources. This is not to say that the analysis determines causality between circumstances and educational benefits (in the same way that a traditional BIA does not establish causality between household incomes and education spending), but it certainly complements the insights provided by the traditional BIA based on household per head income.

Third, the paper conducts an ex-ante simulation analysis of fiscal implications of redistributive interventions aimed at improving the HOI profile in Liberia. In particular, the exercise simulates the distributional consequences of re-assigning public expenditures across different circumstance groups. Also, it examines the consequences of budgetary increases to improve opportunities for all, regardless of circumstance. Critical for this exercise is the inclusion of public spending on education as an ad hoc circumstance for children. Thus fiscal policy acts as both an instrument for improving equality of opportunities as well as an exogenous circumstance to households. This is compatible with the HOI. Molinas et al. (2010) acknowledge that, in specific contexts, policies and circumstances may become the same; even modifying the distribution of circumstances can itself become a policy.

The steps involved in this simulation exercise for Liberia are as follows:

**Step 1: Baseline.** Estimate a logit model whose dependent variable is the opportunity of attending school for children age 6-15 and independent variables include potentially relevant
circumstances (for which information is available): child’s gender; household head’s gender, education and age; region of the household; urban or rural nature of the community where the household is located; number of children in the household; single parent, mother alive and father alive.

\[
\ln\left[\frac{P(T_i = 1)}{1 - P(T_i = 1)}\right] = \alpha + \sum_{j} (\beta_j X_j) + u_i
\]

where \(T_i = 1\) indicates whether the group “i” of children attends school or not and \(X_j\) are the j-circumstances believed to affect school attendance.

**Step 2: Computing opportunities with spending as circumstance.** A new HOI for attending school for children 6-15 is estimated using the same previous circumstances *and* the gross unitary public spending on education, “S”. Depending on available information, the gross unitary benefit may take into account budgetary allocation by level of education and region.

\[
\ln\left[\frac{P(T_i = 1)}{1 - P(T_i = 1)}\right] = \alpha + \sum_{j} (\beta_j X_j) + \delta S + u_i
\]

A new distribution of probabilities of attending school is estimated across children with different sets of circumstances and public spending benefits:

\[
P(T_i = 1)
\]

**Step 3: Policy shock.** Once the parameters of each circumstance determining the opportunity of attending school are estimated, changes or “shocks” to the distribution of public spending on
education are introduced: $S^{\text{sim}}$. These changes consist of increasing or decreasing the gross unitary public transfer implicit in public education provision and/or changes in the distribution of benefits based on different qualifying conditions, such as age, sex or location. The critical—and strong—assumption is that increasing public spending will not lead to increases in the private contribution necessary to attend public schools—neither for those children already enrolled nor for new children not previously attending school who will now attend as a result of the new policy—at least in the short run. A second critical assumption is that there are no economy-wide or inter-sectoral effects. Increasing spending on education may, for example, mean building more schools in rural areas, and hence the parameter associated with location may change as a result. Such interactions are ruled out in the exercise, which merely implies a monetised transfer to beneficiaries. Four policy shocks are considered in this paper: from a purely ‘redistributive’ scenario in which public resources are taken away from certain groups and transferred to other more vulnerable groups (at an assumed zero cost) to scenarios involving a net fiscal cost from removing de facto school fees, reducing non-fee costs or increasing teacher salaries. The resulting new estimated probabilities from this step are:

$$P(T_i = 1)^{\text{sim}}$$

(4)

**Step 4: Attribution.** The difference in the estimated HOIs in step 2 and in step 1 is the impact attributed to the policy shock. The critical assumption in this case is that no household behavioral changes result from the policy change. In other words, the simulation is a pure demand shock that allows no behavioral change. This follows the tradition of static BIA analysis as described in van de Walle and Knead (1995).
A few considerations are in order. Endogeneity between public spending and education enrollment rates is a potential issue. While this is certainly possible (and even desirable from a policy point of view) at a macro or aggregate level, it is not obvious from a household’s perspective. Endogeneity at this level would imply that public policy decisions would be affected by a specific household’s condition. This is at best hard to defend.

A second consideration is the double nature of public spending as a policy tool and as a circumstance. There are three arguments supporting this decision. First, as indicated above, public spending levels and its composition are exogenous to a particular household condition. Households are assumed not to vote with their feet, so to speak, choosing different levels of spending across regions. This would not be a realistic proposition in Liberia, at least not on education considerations. Second, one would argue that the level and composition of spending that an administration decides should not compromise the right of Liberian children to receive education. Third, this case is no different from other less clear-cut candidates for circumstance, as shown in section 2, where the distinction between circumstance and opportunity is not so clear (say, household level of income or consumption).

4. **Data**

4.1. **Educational opportunities**
Previous work in Latin America has focused on five opportunity indicators (see Molinas et al. 2010): access to clean water, sanitation and electricity, completing sixth grade on time, and attending school from age ten to 14. The list is acknowledged not to be exhaustive, but those indicators allow for a comparable and relevant set of measures for 19 countries in the Latin America region. Country-specific work in Brazil, Colombia and Peru has explored a much richer set of indicators, adding to the previous list opportunities such as immunization, micronutrient intake, possession of a birth certificate, access to telephone and Internet and other basic goods and services.

In Liberia, two issues are relevant when selecting indicators for education that can be considered “opportunities”. First, indicators must be available from existing data sources and can be consistently collected over time in order to conduct inter-temporal comparisons. There are two potential data sources, the Demographic and Health Survey (DHS) for 1986 and 2007 and the Core Welfare Indicators Questionnaire (CWIQ) for 2007 and 2010. Given that the DHS of 1986 differs significantly from later DHS surveys and that CWIQ provides more recent information, the HOI analysis for Liberia is conducted using CWIQ. In addition, CWIQ data match the school attendance computed by the Liberian Census 2008 better than DHS data. The CWIQ (2007) draws from a sample of 3,600 randomly selected households located in 300 randomly selected clusters. Table 3 below presents preliminary results of the incidence/coverage rate of opportunities in Liberia for 2007 and 2010.

[Table 3 about here]

The second relevant consideration in the selection of opportunities refers to coverage. Table 3 shows that a number of indicators previously used in Latin American analyses may not be
useful in the Liberian context, as late entry into school appears to be common due to the lingering effects of conflict. Late entry and frequent interruptions also affect timely completion of 6th grade, thus questioning the relevance of timely entrance and/or graduation as an indicator to analyse equality of opportunities. In lieu of that, the proposed indicator for the HOI analysis of educational opportunities is the proportion children of age 6-15 who attend school.

4.2. Relevant circumstances in Liberia

Even when a list of universally accepted circumstances is elusive, circumstances such as gender, parents’ education, incomes and location are widely considered conditions that should not affect access to key public services. Historical conditions in Liberia justify analyzing inequality along other dimensions as well. Ethnicity (or a proxy for that) can be a relevant circumstance in this multi-ethnic country. Given the recent devastating conflict, whether a child has a missing parent and whether s/he belongs to a household that was displaced by the conflict may turn out a relevant circumstance as well. With these considerations in mind, the following list of circumstances are used for HOI analysis: (1) urban or rural residence; (2) region (six in number); and (3) economic status (proxied by asset index) of the household; (4) sex of the child; (5) sex and age of household head; (6) education of household head (number of schooling years); (7) parental presence in the household; (8) number of children in the household, and presence of elderly; (9) exposure to the conflict. Similarly, a child’s birth order may affect decisions on his or her education, as it is shown to do in terms of consumption decisions, school attendance and distribution of chores at home. However, no CWIQ reports this information. We use age as a proxy for birth order. Age is also a relevant circumstance, given that late entry in school is a
common phenomenon in Liberia. Table 4 below reports the basic descriptive statistics for these circumstances.

All these circumstances are available from both CWIQ of 2007 and 2010, except for urban/rural and regions, which are not reported in the CWIQ 2010. Liberia has several ethnic groups. The population is divided in Kpelle 20 per cent, Bassa 14 per cent, Gio 8 per cent, Kru 6 per cent, and 52 per cent spread over 12 other ethnic groups. Kpelle in central and western Liberia is the largest ethnic group. Grebo and Kru are concentrated in the southern area, Bassa in the Grand Bassa area, and smaller groups such as Loma and Gbandi in Lofa (CIA 2012). Since direct information on ethnicity is not available from CWIQ 2007, region may be considered a reasonable proxy for ethnic differences.

The circumstances associated with the impacts of conflict are quite prevalent: around 30 per cent of children do not have both parents and 82 per cent are from households that were displaced by war in the 1990s. Several possible circumstances relating parental presence in the household can be analysed. One possibility is that both parents are alive and living in the household; others include one parent absent from the household, either alive or dead, or both parent absent from the household, either alive or dead. As the effect on opportunities of parental absence may differ from, say, a living father sending remittances home vis-à-vis a dead mother, the most encompassing option is to analyse several circumstances and determine ex-post which is the most determining and influential one. Interestingly, some 74 per cent of households with single parents are led by women. Only 10 per cent of single-parent households have a child with a father not alive. That would point to single motherhood rather than orphan hood as the primary cause for parental absence.
Selected circumstances (as well as opportunities) must be congruently defined over time, that is, for the CWIQ 2007 and 2010. As the computation of HOI requires estimating a logistic model as a function of circumstances, changes in the definitions of circumstances or in the list of circumstances used over time may affect HOI measurement. The variables reported in Table 4 are confirmed to have comparable questions in both rounds.

5. Results

5.1. HOI school attendance in Liberia

The estimation of the 2007 HOI for school attendance among children 6-15 is 59.5 per cent, four percentage points below the observed coverage rate of 63.5 per cent (Figure 1). These two values remained largely unchanged for both the HOI and observed coverage rate in 2010 (60.3 per cent and 65.3 per cent, respectively). In both cases, the difference between HOI and observed school attendance is statistically significant. The penalty (share of access to opportunities allocated in violation of the equality of opportunity principle, see Molinas et al. 2010) is about 4.0 percentage points in 2007 and 4.9 percentage points in 2010, indicating that over time educational opportunities measured through school attendance of children age 6-15 have not become more equally allocated.

Regarding the estimated probabilities of attending school across types of children, for simplicity only eight types of children are reported here based on three circumstances: household head’s education, child’s sex and location of the household in 2007. The remaining
circumstances are considered in the simulations but are not used to discriminate among groups when reporting average results by type. The first four types are opportunity-vulnerable—their estimated probability of attending school given their circumstances is below the observed average access rate, 63 per cent (Table 5). In contrast, the last four types are non-vulnerable as their probabilities are above the observed average access rate. The education of the household head seems to be the most critical factor in the estimated distribution of opportunities: all vulnerable types have parents who have not completed primary education. For the rest of circumstances, vulnerable as well as non-vulnerable types include children both in urban and rural households, and both female and male children.

[Table 5 about here]

5.2. Opp-BIA

Three patterns of education spending—the distribution of monetised benefits accruing to children attending public schools in Liberia per beneficiary (“gross unitary public transfer”), the distribution of private out-of-pocket household spending incurred as a result of attending schools per beneficiary (“unitary private spending”), and the resulting difference between public benefit and private contribution towards school attendance, “net unitary benefit”, again on a beneficiary basis—are now compared (Figure 2). These patterns of public and private spending are compared against the distribution of household wealth and the distribution of educational opportunities, proxied by the estimated probability of attending school conditional on their circumstances (see Table 4 above). The former generates traditional BIA, while the latter an “Opportunity BIA”.
Results from both BIA exercises are staggering. Liberian households make private contributions towards public education that generally exceed the public transfers implicit in the provision of public education (Figure 2a). This is in line with the aggregate contributions towards all educational spending reported for that year by World Bank (2010, PEMFAR): US$12.2 million by the government, US$27 million by households and US$38 million by international donors. From a distributive point of view, unitary private spending towards public education increases by levels of wealth while unitary public transfers hardly change among wealth quintiles. This results in a distribution of net public benefits that is increasingly negative, showing a progressive distribution for the ‘wrong reasons’: progressivity is achieved because of increasing private contributions from households as their wealth increases, rather than by increasing public transfers to poorer households.

This picture is even more dramatic when considering the distribution of educational opportunities (Figure 2b). Once quintiles are computed from the distribution of attending school probabilities among children age 6-15, it becomes clear that children in the bottom two opportunity quintiles (with an expected probability of attending lower than 52 per cent) rarely attend school. This leads to a very small average group gross unitary public spending and unitary private spending in these two quintiles. Children in the third quintile, with an estimated probability of attending school given their circumstances of 52-71 per cent, appear to contribute slightly more than the previous groups. Households from the top two quintiles of the distribution of attending probabilities (71-85 per cent and 85-100 per cent, respectively) clearly contribute privately towards school attendance, more so in the case of the top quintile.

As a result, the Opp-BIA shows the same peculiar progressivity caused by an increasing private contribution among non-vulnerable households and a very low and uniform public
transfer. However, the Opp-BIA shows an even more unequal distribution than traditional BIA. It shows, in fact, that only those most able to pay for public education are likely to attend a public school. Those with a set of circumstances that make them vulnerable are not participating much in the distribution of meager public transfers. By including all children age 6-15 in the distribution of benefits, either attending or not, the Opp-BIA provides a more comprehensive picture than traditional BIA, which only depicts the benefits to those who actually attend school. In doing so, the Opp-BIA analysis presents a bleaker picture of educational spending incidence in Liberia than traditional BIA.

[Figures 2a and 2b about here]

The BIA also provides evidence of the shares of benefits captured by socioeconomic groups. The traditional analysis of shares (Figure 3a) indicates that the pattern of public spending on education in Liberia is clearly not pro-poor. In fact, it follows a very neutral distribution, almost proportional to the share of beneficiaries by quintile (the only exception being a more than proportional concentration of benefits in the third quintile of the distribution of wealth). Incidence analysis based on opportunities (Figure 3b) shows, once again, a bleaker scenario, in which the share of benefits is below the population share for three out of four vulnerable groups of children (groups 1, 2 and 4). The opposite occurs for three out of four non-vulnerable groups of children, 5, 6 and 8, whose share of benefits exceeds their share of children age 6-15. The Opp-BIA confirms that the distribution of benefits is less pro-poor when analysed against opportunities than wealth levels: children age 6-15 belonging to vulnerable categories represent 45 per cent of the total population of children of that age and receive only 37 per cent of public benefits.
5.3. **Redistributive simulations**

Table 6 presents the results of the four simulated scenarios. Simulation 1 has an *increase in government transfers of 70 per cent to all children attending public school*. This amount is the share of the budget that would be required to equalise the current salaries of teachers to regional standards advocated in the Fast Track Initiative, Education for All (see World Bank 2010, PEMPFAR). The simulation increases by 70 per cent the current public transfer accruing to each child attending public school.

Simulation 2 represents an *increase in transfers for all children attending public schools in the form of fee expenses recovery*. In policy terms, the intervention conceived in this scenario is a voucher for each child attending a public school equivalent to the average monetary cost of households’ contributions in the form of implicit fees to the public school (current fees are informal or implicit since they are officially eliminated). This does not necessarily imply that each specific household would be exactly compensated by the amount of fees paid as reported in the CWIQ but by the *average* fees paid by children attending public school at age 6-15.

Simulation 3 is an *increase in transfers for all kids attending public school to compensate for the current non-fee expenses* (books, uniforms, etc.). This corresponds to giving each child in public school a subsidy equivalent to the average monetary cost of non-fee expenses in public and private schools.

Simulation 4 is a *pure redistributive scenario, in which all public resources channeled into beneficiaries of urban public schools are redistributed to children attending rural public schools on a per head basis*. This is not to say that this is a realistic or desirable policy; rather,
the scenario provides a sense of the redistributive potential that such a ‘draconian’ intervention would have.

[Table 6 about here]

Results in Table 6 report the average probability to attend public school for each group before and after the shock, and the respective changes on HOI attributed to the shock. Also, it provides an indication of the additional per beneficiary fiscal cost associated with each scenario. A first finding is that the overall impact in all four simulations is quite limited in magnitude, even when they involve large swings in resources (simulation 4) or large relative increases in transfers (simulations 1 to 3). This implies that even when changes are substantial in relative terms, they are very small in absolute terms: none produces budgetary increases in excess of US$10 million. As a result, no substantive improvement in opportunities in Liberia will occur with levels of educational spending as low as these observed.

A second key result is that the single largest increase in HOI comes from simulation 3, that is, from reducing non-fee expenses from households. This would eliminate the source of monetary contributions for households. This comes at the largest costs as well for the government, at about 92 per cent of the current public budget on education. Since the average cost of non-fee expenses is calculated using an estimate of the household average spending in non-fee school items the population, we are effectively bringing the spending of children in public schools closer to the spending of children in private schools regarding textbooks, uniforms and other school materials. Interestingly, the purely redistributive simulation, simulation 4, causes an overall deterioration in the HOI, as the reduction in urban household HOI is not fully compensated by the increased HOI for rural households (given that many current eligible but
non-participating children in rural areas will improve their situation as a result of the simulated intervention).

Behind the modest estimated average effects on the distribution of opportunities, there are different patterns of winners and losers for each scenario. However, these patterns do not seem to cause large compositional effects among the different types of children. In fact, none of the groups change their vulnerability status as a consequence of the policy intervention. Interestingly, rural groups tend to do better than urban children in all four simulations. In the first three simulations, all groups benefit in net terms, but some benefit more than others. The smallest win in simulation 1 is found among urban female children with non-educated heads. In simulation 2, the smallest win is found among urban female children with educated heads. In simulation 3, urban male children with educated heads win the least. The groups with the largest wins are rural male children, both with educated and uneducated heads. Only simulation 4 has net winners and net losers: rural male children with non-educated and educated household heads and urban male children with non-educated heads, respectively.

6. **Conclusions**

This paper adds to the existing work on equality of opportunities and public policies, linking the recently developed HOI to specific sector interventions. It does so by including the equality of opportunity angle to traditional BIA and by simulating the equity impacts of redistributive interventions on opportunities, rather than on traditional welfare outcomes. The empirical analysis is conducted for Liberia, a case in which both short-term development and longer-term opportunities improvements after a long civil war are paramount policy objectives.
The probability of attending public school in Liberia has improved over time. Household head’s education appears to be very influential in the distribution of children’s educational opportunities. Incidence results indicate that a traditional BIA may not fully pick up the staggering incidence of public resources in education. The opportunity BIA substantiates that children whose circumstances make them vulnerable are very unlikely to attend school and, as such, benefit from any implicit transfer of resources from public education. The main reason appears to be the high private contributions (vis-à-vis public transfers) necessary to attend a public school in Liberia.

Simulation results show that draconian redistributive interventions—without sector changes or changes in circumstances—may lead only modest improvements in the probability of attending school (less than three percentage points) and have little effect on the average vulnerability status of children. Results also show that some types of children defined by their circumstances would not slip into opportunity vulnerability, while other types are not likely to move out of vulnerability following the simulated redistributive interventions. Notwithstanding these results, rural children tend to benefit more than urban from all simulations.

Simulation results need be taken cautiously. The analysis is not intended to provide detailed normative conclusions. Yet, it highlights the fact that some interventions may have a different pattern of winners and losers. These patterns change by intervention, and the costs associated to them also vary substantially. The critical take-away message, however, is that at the level of public spending on education (US$12.2 million), little can be done to improve substantially opportunities among children. In addition, the analysis shows that in spite of large increases in spending a number of circumstances act as serious constraints in determining the probability of enjoying an opportunity. In this respect, by focusing ex-ante on opportunities
rather than outcomes, the analysis underscores that the traditional short-term analysis of welfare outputs may be complemented with a longer-term discussion addressing how to remove critical obstacles to an egalitarian allocation of key public services.

</tbody>
</table>
Assess the status and evolution of equality of opportunities in Latin America.

Compute the HOI defined as:

\[ \text{HOI} = C - P \]

Where \( C \) is the observed coverage for the opportunity and \( P \) is the penalty of inequality of opportunity, computed as:

\[ P = \sum_{k=1}^{\nu} (M_k - \bar{M}_k) \]

Where \( N \) is total population, \( M_k \) is the number of people with access to a good or service within vulnerable circumstance group \( k \), and \( \bar{M}_k \) is the number of people in that group needed to equal the average rate.

Typically:
- parents’ education,
- family per capita income,
- number of siblings,
- presence of both parents,
- gender of the child,
- gender of the household head,
- and urban/rural location

Education dimension:
- completion of sixth grade at proper age (13);
- school attendance of children 10-14.

Housing dimension:
- access to safe water and adequate sanitation;
- access to electricity

Aggregated HOI for Latin American countries as a whole has increased during the last 15 years but there are many disparities among countries and across opportunities.

Circumstances, especially parental education, matter a lot in explaining regional and country-specific distribution of opportunities.

Only a small proportion of HOI improvement over time is due to fairer access of services. Most of the improvement comes from changes in the distribution of circumstances (partially associated to migration).

</thead>
</table>
| School attendance HOI | Measure the equality of the opportunity for school attendance among children 6-15 in Liberia. | $\text{HOI} = \text{C} - \text{P}$  
$\text{P} = \sum_{k=1}^{\nu} (\text{M}_k - \text{M}_k^*)$ | The HOI is a good proxy for an equity-sensitive coverage rate. Circumstances used are relevant key drivers of inequity. A direct property of the HOI is that missing a relevant circumstance does not overwhelm the use of other circumstances: the estimated HOI is an upper bound of the true HOI. | Core Welfare Indicators Survey 2007 and 2010  
Decomposition of key drivers for 2010 results and between 2007 and 2010 are performed.                                                                                                                                                                                                                                                                                                                                 |
| Opp-BIA           | Assess the distribution of public resources among the distribution of opportunities and compare that allocation of resources with the distribution of those resources along wealth. | $\phi(S,w) \text{ vs. } \phi(S,\text{Opp})$  
where $\phi(\text{ })$ is the distribution of public spending $S$ (net of private contributions), across quintiles of wealth, $w$, and opportunities, Opp. | There is no relevant heterogeneity of public spending across groups; we can rely on a constant national unitary benefit. | Fiscal data from public education spending disaggregates level of education but not region, so the unitary benefit is a national average and not region-specific.                                                                                                                                                                                                                                                                 |
| Ex-ante simulations | Attribute changes in estimated HOI due to changes in public spending on education. | **Step 1: Baseline**  
[1] Estimate baseline logit for school attendance age 6-15 conditioned to a number of selected circumstances.  
$$\ln\left[\frac{P(T_i = 1)}{1 - P(T_i = 1)}\right] = \alpha + \sum_{j} (\beta_j X_{ij}) + \mu_i$$ | Step 1: Selected controls are the critical circumstances determining school attendance in Liberia. | No additional data requirements.  
No change in sectoral policies considered following the redistribution of resources (a pure income or demand effect from a new monetized subsidy). |
(iv) Increase in spending targeted to rural children who do not attend school

\[
\ln \left( \frac{P(T_i^* = 1)}{1 - P(T_i^* = 1)} \right)^{\text{sim}} = \alpha + \sum_{j} (\beta_j X_{ij}) + \delta S_{ij}^{\text{sim}}
\]

[5] Estimate the probabilities after the shock and the new post-shock HOI:

\[
P(T_i^* = 1)^{\text{sim}}
\]

Where sim = i... iv

and:

\[
HOI_{sim}
\]

Step 4: Attribution

[6] The differences in the prior and post-shock probabilities to attend school and HOI are attributed to the policy shock

\[
P(T_i^* = 1)^{\text{sim}} - P(T_i^* = 1)
\]

\[
HOI_{sim} - HOI
\]

Figure 1: HOI 2007 and 2010 in Liberia

Quintiles of wealth: Q1: (-1.80 to -0.60); Q2: (-0.60 -0.06); Q3: (-0.06 to 0.38); Q4: (0.38 to 1.09); Q5: (1.10 to 9.78).

Note. There is no direct interpretation of the values of the wealth index. The wealth index is constructed with principal factor analysis (PCA) of information on assets in the household. The source data are a series of dummies where 1 is assigned if the household has the asset (television, car, radio, etc). We construct z-scores of the data and project them onto a new basis using the eigenvectors that decompose the covariance of the data.
