Abstract

Using time series data spanning three decades, Butzer, Mundlak, and Larson examine the determinants of sectoral migration in Indonesia, Thailand and the Philippines. They employ a principal components algorithm to address problems associated with trended and intercorrelated explanatory variables. Migration rates in the three countries are low relative to other developing countries with the consequence of persistent

intersectoral income differentials. Even so, the rate of migration has been responsive to income ratios in each country. The migration rates were also affected by the absorbing capacity of nonagriculture, as indicated by several measures. In contrast to other studies, policy variables consisting of indicators of physical and human capital had little impact on the migration rate separate from that captured by relative incomes.

This paper—a product of Rural Development, Development Research Group—is part of a larger effort in the group to assess the role of the rural sector in economic growth. The study was partially funded by the Research Support Budget under the research project “Dynamism of Rural Sector Growth” (RPO 683-06). Copies of this paper are available free from the World Bank, 1818 H Street NW, Washington, DC 20433. Please contact Pauline Kokila, room MC3-604, telephone 202-473-3716, fax 202-522-1151, email address pkokila@worldbank.org. Policy Research Working Papers are also posted on the Web at <http://econ.worldbank.org>. The authors may be contacted at rbutzer@fas.harvard.edu, mundlak@agri.huji.ac.il, or dlarson@worldbank.org. Intersectoral Migration in Southeast Asia: Evidence from Indonesia, Thailand, and the Philippines

Rita Butzer, Yair Mundlak, and Donald F. Larson

Introduction

Beginning with Lewis (1954), the flow of labor resources from agriculture has been an important consideration in models of economic development. Since Todaro's 1969 article, well-formulated models have been available to guide empirical measurement of the process of sectoral migration. In practice, rates of migration and rates of natural population growth tend to be similar, so the accumulated effects of migration occur over decades. However, using long time-series measures of sectoral migration poses special difficulties for researchers since some of the explanatory variables are trended and intercorrelated. Omitting correlated variables runs the risk of specification error, a problem formulated by Theil in 1957. In this paper we describe the flow of labor resources from agriculture to other sectors of the economy in Indonesia, Thailand, and the Philippines over three decades, and examine factors that determine the rate of migration. To mitigate the problems associated with intercorrelated variables, we employ principal components, using the algorithm given in Mundlak (1981), which imposes parameter restrictions as a substitute for the elimination of specific variables.

The three countries we study are geographically close and share similar climate and other characteristics; however growth experiences have differed. In a companion paper (Mundlak, Larson and Butzer, 2002) we consider sources of growth and productivity in the three countries in which the stock of agricultural labor plays a key role. In all three countries, economic growth and growth in agricultural income have been associated with an out-migration of labor from agriculture. However, as with growth, country experiences differ in key ways.

The share of agriculture in total employment is shown in figure 1. The shares are very high in the 1960s and 1970s (over 50 percent for Indonesia and the Philippines and over 70 percent for Thailand) and fall over time. Nonetheless, in the late 1990s, the agricultural sector still employed nearly 40 percent of workers in the Philippines and Indonesia and 50 percent in Thailand. In developed economies, these shares level off at 2-3 percent (Larson and Mundlak, 1997). While the shares in Indonesia, Thailand, and the Philippines have decreased rather steadily over the past three decades, the pace of the allocation of labor resources from agriculture to other sectors of the economy has been relatively slow, with some indications of speeding up in the past decade. We will examine this process of reallocation of labor.

Migration From Agriculture

Framework

The change in the sectoral composition of the labor force is the outcome of migration from agriculture conditioned by births and mortality rates. We describe the

analysis of this process, using the framework in Larson and Mundlak (1997) and Mundlak (1979). These authors also provide a review of the literature relevant to the approach taken in this paper. We summarize here the material pertinent for the empirical analysis. Intersectoral labor allocation is analyzed within the framework of occupational choice. The postulation is that at any time the individual maximizes his remaining-life utility by, among other things, choosing his occupation. The choice is made from a feasible set of occupations, which are characterized by the trajectory of their income, and the uncertainty attached to it. We concentrate on the binary choice between agricultural and nonagricultural work. The two sectors are not homogeneous, but in most of the discussion this fact is ignored. As nonagricultural employment often requires moving to other areas, the cost of migration involves additional elements to those attached to the change of occupation alone.

Data on off-farm migration in Indonesia, Thailand, and the Philippines are not available; thus they are inferred from changes in intersectoral allocations of labor. It is assumed that without migration, agricultural labor would grow at the same rate as total labor. Deviations from this rate are attributed to migration. Migration was calculated as

$$\begin{aligned} M_t &= (L_{At-1} * (1 + n_t)) - L_{At} \\ m_t &= M_t / L_{At-1} \end{aligned} \quad (1)$$

where M is the number of migrants (outflow of workers from agriculture to nonagriculture), L_A is agricultural labor, n is the rate of growth of the total labor force, and m is the ratio of migrants to agricultural labor. In practice, we calculate n from $n_t = (L_t - L_{t-1}) / L_{t-1}$, where L is total labor. Similarly, define the growth rate of the agricultural labor force as $n_{At} = (L_{At} - L_{At-1}) / L_{At-1}$, then $m = n - n_A$. Thus the rate of migration out of agriculture is the difference between the growth rate of total and of agricultural labor.

Ideally, we would like to use data on labor to calculate migration rates as shown above. However, the country sources do not report data on agricultural labor, but rather agricultural employment. Annual sectoral labor data are available from the Food and Agriculture Organization (FAO) and the World Development Indicators (WDI) of the World Bank, which are constructed from census data. Such data, however, are collected every ten years and the annual series are obtained with straight-line interpolations. Thus migration rates calculated from these data do not actually measure the annual variation that we hope to explain. We therefore have chosen to use employment data from the country sources to calculate migration rates. This choice is the outcome of the data limitation, but is not an ideal one.

The constructed migration series are plotted in figures 2-4. The migration rates are volatile, to the point where it is difficult to discern any trends. It is to be noted, however, that most of the observations are in the positive part of the graphs, which indicate positive migration over the entire period. The volatility comes from two sources: First the use of data on employment rather than data on labor brings the demand for workers (and hence, shocks to that demand) into the constructed migration series, and second, annual data tend to be more erratic; nevertheless the trend still prevails. This is seen in table 1, which presents decade averages of the migration rates. The migration

rates are relatively low by international standards and are consistent with the slow change in the share of agriculture in employment discussed earlier and seen in figure 1. The average migration rates are greater than 2 percent in only two cases (Indonesia and Thailand in the 1990s). Comparing the rates with those for Asian countries from the study by Larson and Mundlak (1997), we see that migration was somewhat slower in Indonesia, Thailand, and the Philippines than in other Asian countries.¹ We should also note from this table the considerably lower migration rates in the 1980s in Thailand and Indonesia. We now turn to identifying factors that determine these rates of migration.

Formulation

The analytic framework is summarized in the form of the migration equation:

$$m_t = \beta_0 + \beta_1 \ln(RI_{t-1}) + \beta_2 \ln(RL_{t-1}) + \beta_S S_{t-1} + \mu \quad (2)$$

where m is defined above, $RI = I_N/I_A$ is the income ratio (the ratio of GDP per worker in the nonagricultural sector to that in the agricultural sector), $RL = L_N/L_A$ is the ratio of employment in the nonagricultural sector to that in the agricultural sector, and S represents other attributes and exogenous state variables.

We isolate the income and labor ratios from the other variables for the following reasons. The income ratio is assumed to be the major incentive faced by the potential migrant. In applying the formulation to the market, we need to consider the size of the labor force in the two sectors. The number of migrants depends on the size of the labor force in agriculture (the origin); the larger is the labor force in agriculture, the more migrants can be expected under a given economic environment. The actual number may also depend on the ease of finding work in nonagriculture. In the absence of strong unemployment there, it is expected that the larger is the labor force in the destination, the easier it is to get a job. The formulation assumes that the migration rate depends only on the composition of the labor force (the ratio of labor in nonagriculture to agriculture), and not on the size of the total labor force. The variables covered by S are discussed below.

Variables and Data

The choice over whether to migrate is strongly influenced by incentives, the main one being sectoral income. The basic idea is that labor, like other resources, flows from low to high-income occupations.² As such, this is a qualitative property, and to test it would require a comparison of data with and without a sectoral income gap. The data does not appear in this dichotomy form, and instead it shows variability. The empirical analysis, as formulated in equation (2), is designed to examine the impact of such variability on the migration rate. It thus tests a much stronger proposition:

Proposition: The larger is the income gap between the sectors, the stronger is the migration rate. In other words, the income gap affects the pace of the resource allocation.

¹ Migration in Indonesia, Thailand, and the Philippines was also far slower than in Latin America where rates were close to 2 percent in the 1960s, and over 2 percent in the 1970s and 1980s (Larson and Mundlak, 1997).

² Basically, this is the essence of the dual economy model of Lewis (1954) and Ranis and Fei (1961).

We measure the incentive by income and not by wages. When it comes to long-term decisions, such as the migration out of agriculture, income is thought to be a more informative measure of the future prospects than wages. Wages are the more important component of income, but not the only component. The nonwage component of income (for example, the rent on land and returns to capital, both physical and human) may be influential in the migration decision. In addition, in our particular case there is a basic problem with the wage data. As indicated by Mundlak, Larson, and Butzer (2002), the published wages are daily rates. To convert them to annual figures, it is necessary to know the number of working days, but this information is not available.

The intersectoral income differential is measured by the ratio of income in nonagriculture to that in agriculture.³ Evidence from cross-country studies shows that as countries develop, the income differential decreases. “In middle and high income countries, the [income] ratio is almost equal to 1 and, as the data show, this statement was as true in 1950 as it is today.” (Larson and Mundlak, 1997). This finding summarizes a long-run process whereby migration of labor from agriculture to nonagriculture will lessen the gap in productivities. As the supply of labor in agriculture decreases, the shadow price of agricultural labor will rise, leading to investment in labor-saving techniques in agriculture. Increased stocks of capital (human and physical) enhance the productivity of the labor remaining in agriculture.

Our current analysis deals with annual variations, and in this sense differs from the cross-country analysis based on period averages, which are subject to less variability. Figure 5 shows that the productivity in nonagriculture has been much higher than in agriculture. In part this may reflect the problem of the labor data, which may overstate the labor in agriculture and understate that in nonagriculture (for details see Mundlak, Larson, and Butzer, 2002). We continue here to review the data ignoring this possible data problem. An increase in the income differential occurs when nonagricultural productivity grows at a faster rate than agricultural productivity. For most of the study period agricultural productivity increased, but at a slower pace than that of nonagriculture. It is important to keep in mind that the productivity measure is an outcome of the effect of the economic environment on output and the labor input. Because the economic environment varied across countries and over time the pattern of the income gap was not uniform for the three countries.

In Indonesia, the difference in the sectoral incomes actually increased throughout the 1970s and 1980s, peaking in 1990 before decreasing back to the early 1980s levels, in spite of consistent positive growth in agricultural GDP. Agricultural productivity in Indonesia increased by 25 percent between 1971 and 1980, but then remained stagnant throughout the 1980s. Agricultural GDP was increasing, but at the same rate as agricultural employment. Nonagricultural sectors grew rapidly after 1985, widening the existing income differential. Since 1990, the gap decreased as agricultural productivity increased by over 40 percent (due to decreases in agricultural employment) before the crisis in 1997.

³ Income is calculated as GDP (in constant prices) per worker, where nonagricultural GDP is the difference between total GDP and GDP in agriculture (and similarly for nonagricultural employment).

The sectoral income gap is extremely high in Thailand and has remained so throughout the past three decades, though it has been declining steadily in the later 1990s. Agricultural productivity in Thailand increased by 17 percent in the 1970s and by only 12 percent in the 1980s as the commodity boom ended and prices stagnated. The nonagricultural sector grew rapidly after the influx of foreign direct investment in the late 1980s. From 1990-1999, agricultural employment decreased, and agricultural productivity increased by over 55 percent, contributing to the decline in sectoral income differentials.

In the Philippines the income ratio increased over part of the study period (1975-1984) and stayed above 2.5. Much of the movement in the income ratio was due to slow growth in nonagricultural productivity, particularly since the early to mid-1980s when the Philippines experienced a series of political and economic crises. Agricultural productivity in the Philippines increased 25 percent over the past three decades, but most of the growth occurred in the 1960s as a result of the green revolution. Agricultural GDP actually decreased in the early 1980s. Agricultural employment has continued to increase throughout the study period. Still, the gap declined from 1983 on.

To sum up, there is a tendency for the income gap to decline in the more recent years in the three countries. This was still not sufficient to affect the decade averages of the gap as shown in table 2, but it is expected that these countries will follow the development that took place in other countries and the gap will eventually decrease substantially. We can compare these trends to those for Asian countries in the Larson and Mundlak (1997) study. The slow rate of migration from agriculture to nonagriculture plays a significant role in these trends. Migration has not yet been sufficient to close the income gap between the sectors. Conversely, given that the income gaps are still rather large, it is not surprising that migration rates have not decreased in the 1990s.

The vector S in equation (2) consists of other variables that may affect the migration decision. We think of two groups, one related to incentives, and the other consists of variables representing infrastructure, which may bear on the cost of migration. The latter group contains trended variables, whereas the migration rates show high variability. Thus the onus of the explanation is on the first group. We therefore list several variables that might have affected migration, and leave it for the data to determine their relevance in our case.

As for the incentives, the income ratio may not fully summarize the opportunities and their stability. We therefore consider other variables that reflect the attractiveness of the two sectors. It is worth noting at the outset that several of the variables we consider have a direct role in determining agricultural income and productivity, which we attempt to measure in Mundlak, Larson, and Butzer (2002). However, for reasons given below, we expect these factors to play an additional role in migration as well.

A natural variable is the terms of trade of agriculture as measured by the ratio of sectoral prices, agriculture to nonagriculture.⁴ The price ratio affects the relative profitability of agriculture, and thus a decline in the price is expected to encourage migration. The condition in agriculture can also be viewed in the ability of the

⁴ The price ratio is the ratio of the GDP deflator in agriculture to that of nonagriculture. The GDP deflator is derived from the ratio of GDP in nominal prices to GDP in constant prices.

agricultural sector to support its expanding labor force. For that purpose we use the ratio of agricultural population to agricultural land as a measure of agricultural density. It is expected that the more densely populated the agricultural sector, the greater the incentive to migrate out of agriculture. This can be viewed as a measure of the push side.

On the pull side, we try several measures related to the prospect of finding work in nonagriculture. Unutilized capacity in nonagriculture is approximated by the difference between the peak of previous per capita output and current per capita output, divided by the peak value. If the current value exceeds the peak value, unutilized capacity is zero. An alternative measure is the growth rate of output in the nonagricultural sector. Periods of fast growth are presumably more attractive for migration. A more direct measure is the growth rate of the nonagricultural labor force. We also tried the difference in the growth rates of output in nonagriculture to that in agriculture.

Turning to the second group of variables, the rate of migration is also affected by the cost of migration. This cost is negatively related to the degree of integration of the rural areas with labor markets. Such integration depends on the state of the physical infrastructure, such as roads and telecommunications. Education may also reduce the cost of migration, probably through the ability to obtain and digest information, thus we expect a positive effect on migration. The education variable also reflects the demand preferences for skilled labor. Labor and technology are not homogeneous and with the changes in technology, there is an increasing demand for skilled labor; this supplements the effect of education on the migration cost.

Certain public health issues, such as the spread of infectious diseases, can be viewed in terms of the cost of migration and the incentives to migrate. The prevalence of roads, telecommunications, education, and health depends on the investments in such activities. This investment originates mostly in public sector, and we therefore refer to this group as the policy variables. The impact of the public goods on the migration rate, however, might be ambiguous. On the one hand they reduce the migration cost, but on the other hand they increase the labor productivity in agriculture, as well as in nonagriculture, and thereby might reduce the income gap. In that case, the net effect is uncertain. Moreover, the empirical scope for these variables in time-series analysis of the migration equation is rather limited. Migration is subject to annual variations, whereas these explanatory variables are strongly trended and highly intercorrelated.

Regression Results

The migration equation was estimated separately for each country, and the results are reported in tables 3-5. The time period varied depending on data availability. The explanatory variables were lagged one period and expressed in natural logs, except when noted. As we saw in earlier figures, migration rates for some years were negative, and therefore the dependent variable is migration rate (m). Recall that the migration rate was calculated from the employment data, rather than the labor force, and the resulted series are volatile.⁵ Since some of the explanatory variables are trended and intercorrelated, the explanatory power of the regressors is not high. The regression did not sustain all the

⁵ The data problems are discussed in Mundlak, Larson, and Butzer (2002).

contemplated variables and the exercise amounted to a search of relevance of the various variables in explaining the data. We report results obtained by OLS, and by principal components (PC). As mentioned earlier, the latter was used to impose restrictions on the parameter as a substitute to the elimination of specific variables. Such a procedure reduces the specification error due to omission of regressors (Theil, 1957). The statistical rank reported in the tables is obtained as the difference between the number of regressors and the number of restrictions imposed on the parameters.⁶ Throughout, the Durbin-Watson statistics did not flag a serial correlation problem.

The most important, and most robust, result is the positive impact of the income ratio on the migration rate. The numerical value of the income-ratio coefficient varied somewhat in the various experiments, but on the whole the coefficient was significant. This is empirical validation of the proposition stated above and is consistent with other studies with a similar specification. The elasticity with respect to the income ratio (computed at the mean value of the migration rates) varied in the range of 10-12 in Thailand, 4-8 in the Philippines, and was 7 for Indonesia.⁷ These are high values, but it should be noted that the impact of a 10 percent change in the migration rate on the sectoral employment is by far smaller. We turn now to review the role of the other variables.

The labor ratio was practically irrelevant with a few exceptions, one of which is shown for Thailand. But even there the importance is marginal. Instead, what seems to be important is the absorbing capacity of nonagriculture. This is revealed by several indicators. The unutilized capacity in nonagriculture was important in Indonesia and in Thailand. In most of the period, the measure of unutilized capacity was zero, and as a result the mean value is low, but in some years it was quite high. The peak value for this variable in the study period was 0.12 in Thailand and 0.16 in Indonesia. The elasticities reported in the table are calculated for the mean values. In years of high-unutilized capacity in nonagriculture, the elasticities would be considerably higher. For the extreme values reported above for the study period, the elasticities would be higher by an order of magnitude of tenfold.

In the Philippines, the nonagricultural sector did not develop fast enough to attract and absorb labor from the agricultural sector, an issue raised by Balisacan, Debuque, and Fuwa (2002). To take account of this fact, we used data on the growth rate of employment in the industrial sector. This variable has a strong positive effect on migration.⁸ We did not have a similar measure for the other countries. We therefore used the growth rate of nonagricultural employment. This variable enters the calculation

⁶ The PC method used followed the algorithm in Mundlak (1981). Unless indicated otherwise, the level of significance was 10 percent. A statistical rank of 3 means that three linear combinations of the variables summarize the information contained in the regressors.

⁷ Let $m = b \ln x$, then the elasticity of m with respect to x is $\partial \ln m / \partial \ln x = b / m$. The results reported in the paper are obtained at the mean value of m .

⁸ The labor data in the Philippines is reported for three sectors: agriculture, industry, and services. Thus, industrial employment is not the same as nonagricultural employment. In 1960, approximately 50 percent more people were employed in Services than in Industry. By 1971, employment in Services was double that in Industry, and by the late 1990s, it was nearly triple.

of the migration rates, and therefore its effect should be interpreted with caution. This was done for Indonesia where the coefficient is positive and significant. Note however, that its introduction did not affect the coefficient of the income ratio much, and its effect on the other coefficients is not substantive. The interpretation is that the variable picked up some of the noise in m that comes from the use of the employment data in the calculation of the migration rates. The results for Thailand were less meaningful. We also tried the difference in the growth rates of output between nonagriculture and agriculture. This variable had a marginal positive effect only for the Philippines.

The terms of trade of agriculture, measured by the price ratio, were relevant in the Philippines, where the variable varied much over the study period, unlike in Thailand and Indonesia. The sign of the coefficient is negative, meaning that the migration rate is higher in years when the terms of trade of agriculture are low. We tried a population density variable (the ratio of population to agricultural land). The variable did not have explanatory power. Inflation was empirically relevant in Indonesia with a positive coefficient; it seems that the heating up of the economy was supportive to migration. There can be various interpretations to the role of the inflation rate, but the finding is not so strong that it justifies diving into the discussion of this subject here.

Finally, the public good, or policy, variables discussed above had little impact. These variables are trended and thus had only weak correlations with the migration rate. The most pronounced effect is education in the Philippines, obtained in the PC regression. It was possible to force some of the policy variables in other regressions using the PC procedure, but with a cost of reducing the level of explanation. This means that the contribution of these variables to the explanation, conditional on the other regressors is negligible, or negative. This result may reflect the data problem, but it may also be due to the fact, discussed above, that the impact of the public goods on the migration rate might be ambiguous. In a cross-country study (Larson and Mundlak, 1997), education showed a robust positive impact on the migration rate. That study does not include measures of physical infrastructure, such as road length, or health conditions, so it is not strictly comparable to the current study. It does, however, contain year and geographic dummies that may confound some of the impact of the infrastructure. To conclude, we refrain from generalizing our empirical results on the role of the policy variables.

Conclusions

The labor migration from agriculture is related to the dynamics of sectoral allocation of labor. The paper examines the process in Indonesia, Thailand, and the Philippines. The migration rates from agriculture to nonagriculture are relatively low compared to those of other countries; thus labor surpluses have not been reallocated at a fast pace to other sectors of the economy. The effect of these low migration rates on the persistence of the intersectoral income differentials is obvious. Even so, the rate of migration has been responsive to the income ratios in each country. The migration rate was also affected by the absorbing capacity of nonagriculture, as indicated by several measures. The policy variables consisting of indicators of physical and human capital had little impact on the migration rate separate from that captured by relative incomes.

Unfortunately, the data yield migration series that contain a considerable amount of variability for which we have not been able to account. This variability may be due to data problems or perhaps to economy-wide shocks. This remains part of the puzzle of migration in Indonesia, Thailand, and the Philippines.

Appendix: Data Sources

Thailand

Gross Domestic Product (Agricultural, Total) – The agricultural GDP series includes Forestry & Fishery, but does not include Simple Agricultural Processing Products. National income accounts were obtained in constant and current market prices (baht) from the Office of The National Economic and Social Development Board (NESDB).

Employment (Agricultural, Total) – Data on employment comes from the National Statistical Office, *Report of the Labor Force Survey*. Round 2 (July-September) was used for 1969-1983, and Round 3 (August) was used from 1984 on. No data was reported for 1970, so straightline interpolation was used to estimate the data. For 1961-1968, data obtained from Coxhead and Plangpraphan (1998) were used.

Philippines

Gross Domestic Product (Agricultural, Total) – The agricultural GDP series includes Forestry and Fishery. National accounts were obtained in constant and current market prices (pesos) from the Economic and Social Statistics Office, National Statistical Coordination Board (NSCB).

Employment (Agricultural, Industrial, and Total) – Data on employment comes from the Labor Force Survey, National Statistics Office. When available, data from the October survey were used. Sectoral data were not reported in 1964, 1969, and 1979. For these years, the ratios of sectoral employment to total employment were estimated using straightline interpolations. Agricultural and industrial employment figures were then calculated from these estimates.

Education – Economy-wide human capital is proxied by the mean school years of education of the total labor force. This data series was constructed by Nehru, Swanson, and Dubey (1993) from enrollment data using the perpetual inventory method and is available up to 1987. Data for 1988-1998 are forecast by fitting the series using an OLS regression of human capital on time.

Indonesia

Gross Domestic Product (Agricultural, Total) – The GDP series in current and constant prices were obtained from various issues of *Statistik Indonesia* (the Statistical Yearbook of Indonesia), Badan Pusat Statistik (BPS). The agricultural GDP series includes Forestry & Fishery.

Employment (Agricultural, Total) – The *National Labour Force Survey* contains data on population 10 years of age and over who worked by main industry. These were obtained from various issues of *Statistik Indonesia*, BPS. Data for the missing years of 1972-1975, 1979, and 1983-1984 were estimated using straightline interpolations of the ratio of agricultural employment to total employment, as well as the total employment series. Agricultural employment was then calculated from these estimates. Employment data reported for 1998-1999 were for population of age 15 and over, so the annual changes in this series were calculated and applied to the previously mentioned employment series (age 10+) to obtain estimates for these years.

Consumer Price Index – Data on the consumer price index of 17 capital cities in Indonesia are reported in the *International Financial Statistics* of the IMF. Data were converted to a base year of 1993.

Education – Economy-wide human capital is proxied by the mean school years of education of the total labor force. This data series was constructed by Nehru, Swanson, and Dubey (1993) from enrollment data using the perpetual inventory method and is available up to 1987. Data for 1988-1998 are forecast by fitting the series using an OLS regression of human capital on time.

Figure 1: Agriculture's share of total employment

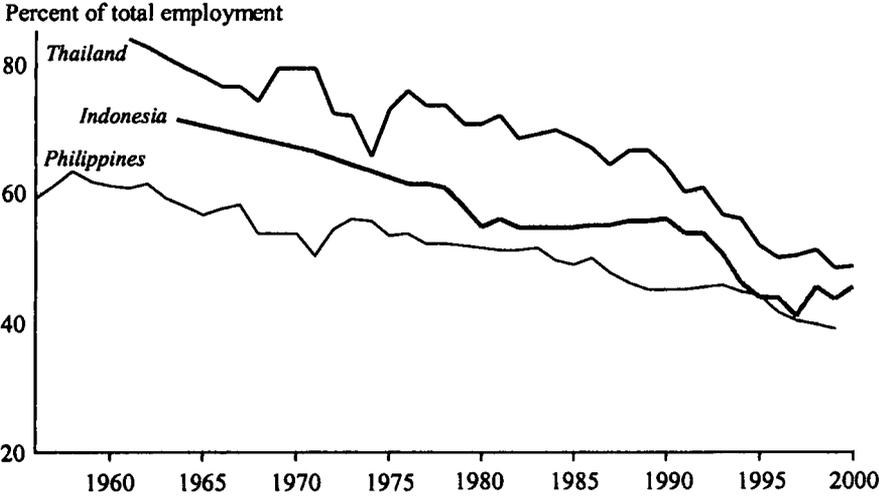

Figure 2: Migration from agriculture in Thailand

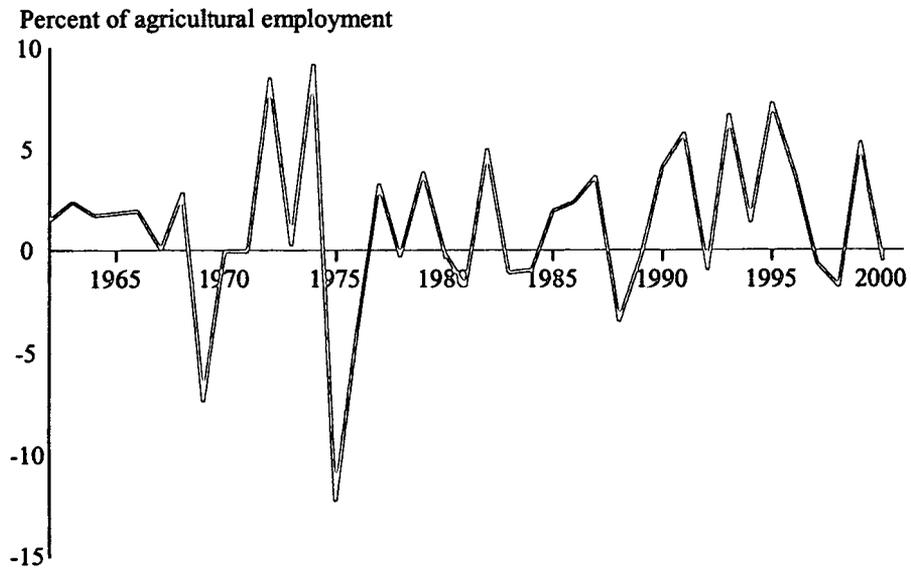

Figure 3: Migration from agriculture in the Philippines

Figure 4: Migration from agriculture in Indonesia

Figure 5: Ratio of average incomes per worker, non-agriculture to agriculture

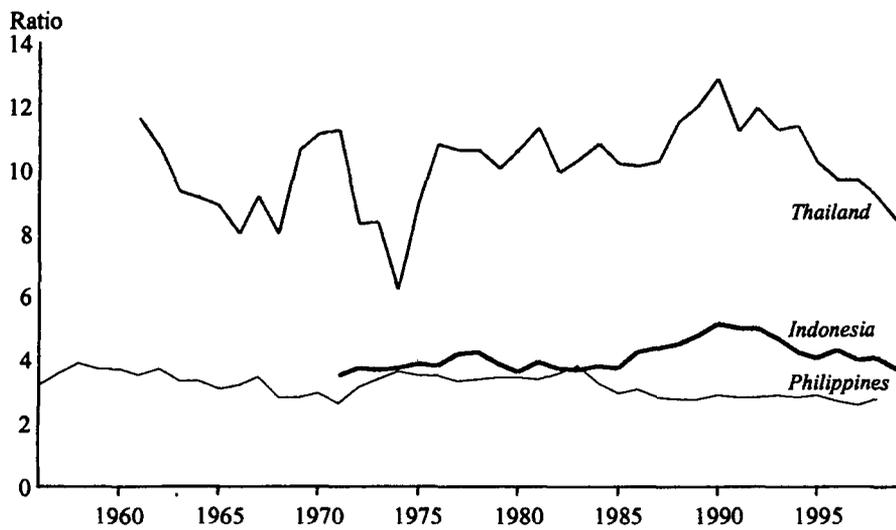

Table 1: Average migration rates for selected periods

	Decade averages				Period of analysis	Period averages
	1960s	1970s	1980s	1990s		
	Percent per annum					Percent per annum
Thailand	0.61	0.89	0.55	3.09	1962-99	1.32
Philippines	1.32	0.35	1.39	1.45	1962-98	1.11
Indonesia		1.72	0.39	2.27	1972-99	1.44
Asia	1.07	1.40	1.80	n.a.		

Note: Asia decade averages taken from Larson and Mundlak (1997).

Table 2: Decade average income ratios

	1960s	1970s	1980s	1990s
Thailand	9.47	9.63	10.69	10.57
Philippines	3.29	3.29	3.19	2.79
Indonesia		3.88	4.07	4.44
Asia	3.37	3.31	3.57	

Note: Asia decade averages taken from Larson and Mundlak (1997).

Table 3: Principal components regression results for Thailand, 1962-99

	estimate	t-score	estimate	t-score
intercept	-28.59	-3.43	-34.17	-3.52
income ratio	13.59	3.59	15.42	3.68
employment ratio	1.64	3.59		
unutilized capacity	-9.13	-3.59	-12.78	-0.52
R-square	0.26		0.30	
D-W statistic	2.17		2.04	
statistical rank	1		2	
<i>Means</i>				
migration	1.322		1.322	
unutilized capacity	0.009		0.009	
<i>Elasticities</i>				
income ratio	10.28		11.67	
employment ratio	1.24			
unutilized capacity	-0.06		-0.09	

Note: the elasticities were calculated at mean migration rates.

Table 4: Principal components and ordinary least squares regression results for the Philippines, 1962-98

Estimation method	OLS		OLS		PC	
	estimate	t-score	estimate	t-score	estimate	t-score
intercept	-4.45	-0.91	-18.21	-1.93	-17.20	-1.87
income ratio	4.31	0.99	8.50	1.74	5.58	1.25
ratio of gdp deflators	-2.84	-0.77	-5.32	-1.47	-6.79	-2.19
growth rate of industrial employment	0.21	2.62	0.16	2.07	0.14	2.19
mean years of schooling			4.69	1.69	6.01	2.36
growth rate differential			0.22	1.71	0.17	2.54
R-square	0.22		0.35		0.30	
D-W statistic	2.15		2.08		2.10	
statistical rank					3	
significance level					0.15	
<i>Means</i>						
migration	1.112		1.112		1.112	
growth rate of industrial employment	3.308		3.308		3.308	
growth rate differential			1.338		1.338	
<i>Elasticities</i>						
income ratio	3.88		7.64		5.02	
ratio of gdp deflators	-2.55		-4.79		-6.11	
growth rate of industrial employment	0.63		0.49		0.41	
mean years of schooling			4.22		5.40	
growth rate differential			0.27		0.20	

Note: the elasticities were calculated at mean migration rates.

Table 5: Principal components and ordinary least squares regression results for Indonesia, 1972-99

Estimation method	OLS		OLS		PC	
	estimate	t-score	estimate	t-score	estimate	t-score
intercept	-13.78	-1.60	-11.55	-1.64	-18.42	-5.66
income ratio	10.22	1.73	2.88	0.45	10.80	6.17
unutilized capacity	-35.96	-2.46	-35.89	-2.69	-12.12	-2.18
inflation rate	0.11	1.96	0.09	2.21	0.05	1.85
mean years of schooling			3.88	1.61	0.90	2.60
growth rate of nonagricultural employment			0.55	4.84	0.56	6.06
R-square	0.31		0.67		0.61	
D-W statistic	2.04		2.38		2.54	
statistical rank					2	
significance level					0.10
